ABSTRACT

Rocket attacks on civilian and military targets, from both Hezbollah (South Lebanon) and Hamas (Gaza strip) have been causing a major operational problem for the Israeli Defense Forces for over two decades. In recent years, U.S. forces are facing similar attacks in Afghanistan and Iraq against both remote military outposts and in the heart of Baghdad ("Green zone"). The insurgents are using mortars and short range rockets, whose launch platforms have very low signature prior to launch. The insurgents have adopted a "shoot and scoot" tactic making it hard to detect them in time to retaliate effectively. In this thesis we present a new analytic probability model, that addresses this tactical situation. The defender's decision tradeoffs are explored and quantified. A new counter mortar/rocket tactic is suggested and explored using the probability model. An extended simulation model is developed to explore the situation when the defender is using a sensor that is subject to false positive detections.

EXECUTIVE SUMMARY

The Operational Problem

Terrorists and insurgents are using short range mortars and improvised rockets against U.S. and Israeli Defense Force (IDF) civilians and military targets. The weapons' low signature makes them hard to detect before the actual launch. The mortar tube or the rocket launcher are light and easily transported, and may be disposable after the firing. This allows the attackers to use a "shoot and scoot" tactic making it hard to detect them in time to retaliate effectively.

The Scenario

We consider the following situation. An attacker fires a salvo of several rockets at a defender. The defender uses a ground sensor to detect the rocket launches. Following a certain number of rocket-launch detections, the defender launches a missile aimed at the attacker. The attacker stays in position at the launching location until he has fired the last rocket in the salvo. Soon after the last rocket of the salvo is fired, the attacker disappears from the launching site and becomes invulnerable to the defender's missile. Since it takes some time for the missile to reach its destination, the missile may reach the attacker's launching location after the attacker has escaped, in which case the defender has failed his objective to kill the attacker. Therefore the defender has a tradeoff between launching his missile earlier but less accurately and, launching it later with more accuracy, but at the risk of being too late.

The defender's firing rule determines how many rocket detections need to be acquired before launching the missile.

The Model

The analytic model is described by the following equation:

$$P_{success} = \sum_{k=1}^N P\{missile\ launched\ on\ k^{th}\ rocket\} \cdot P\{missile\ hit\ on\ time\ | k\} \cdot P\{attacker\ is\ killed\ | k\ \&\ timely\ hit\}$$

Where N is the number of rockets in the salvo. In the analytic model we assume that the ground sensor has no false positive detections. Later on this assumption is relaxed in a simulation implemented in SimKit.

Current Tactic: “Aim first – Shoot later”

Typically, to counter rocket, artillery or mortar fire (henceforth called “rockets”), a ground sensor (e.g., radar) is assigned to continuously scan a “hot” sector, detect enemy rockets, and locate the position of the attacker. To allow the use of high precision weapons against the rocket launchers, and in order to reduce collateral damage, the defender’s ground sensor attempts to gather as much information as possible about the location of the launchers before the defender retaliates.

The ground sensor tries to track the trajectory of a rocket for as long as possible. The estimated trajectories of the rockets are recorded and averaged and, based on these averages, the launcher location is estimated. The decision to open counter-fire aimed at the launcher may depend on the accuracy of the location estimation. The larger the number of rockets observed by the ground sensor, the larger the sample size of the estimated trajectories and thus the higher the accuracy of the launcher position. However, while this tactic of “wait-and-observe” increases the accuracy of the location estimate, it consumes valuable time, during which the attacker may escape and thus render the counter-fire useless. A firing rule in this tactic will call for a missile launch after as many rocket detections as possible.

Suggested Tactic: “Shoot first – Aim later”

To mitigate the possibility that the counter-attack will be executed too late, we propose a new tactic. This tactic may require a new type of weapon.

Consider a single rocket launcher. Following the first detected rocket in the attacker's salvo, the defender's ground sensor obtains an initial rough estimate of the launcher's location and immediately launches a precision guided missile (PGM) directed towards that estimated location of the attacker's launcher. While the prompt response will save precious time, this is not enough; accuracy is also needed for effective counter-fire. The accuracy will be achieved by updating the location estimates of the attacker, while the PGM is airborne, based on detection of subsequent rockets in the salvo. This may be achieved either by sending information gathered by the ground sensor to the missile via uplink or using a second sensor onboard the missile. A firing rule in this tactics will call for a missile launch after as few rocket detections as possible. A firing rule is defined as the number of detections recorded in a certain time period.

Conclusions/Results

A model for evaluating the effect of various firing rules has been developed and the conditions for the suggested tactic success are presented. The suggested tactic has been evaluated and explored under several assumptions. The defenders tradeoffs between firing rules have been quantified in terms of the probability of killing the attacker, and the rate of incidents where false salvos are incorrectly identified, which result in wasted missiles and possibly collateral damage.

ACKNOWLEDGMENTS

I would like to thank my thesis advisors Professor Moshe Kress and Assistant Professor Roberto Szechtman for making the writing of thesis a fun and enriching experience.

I would like to thank my fiancé Sheran Goldberg (soon to be Harari) for her support and love. For encouraging me to put in many hours into my work, and for listening to me talk about it. For being so understanding when those hours came at the expense of precious time together and for being so patient when my talking got long...

THIS PAGE INTENTIONALLY LEFT BLANK

I. INTRODUCTION

Citizens in Israel have been under the threat of short-range rockets and mortar fire for more than two decades. Hezbollah, a terror organization based in South Lebanon, has used “Katyusha” (107/122 mm) rockets to target towns and cities on Israel’s northern border since the 80s. These attacks have been an ongoing security problem of varying intensity over time, from periods of sporadic shootings, to periods of intense bombardments lasting days and weeks.

This form of terror attacks aimed mostly at civilian concentrations reached a peak during the Second Lebanon war (July – August 2006). During that one-month period, over 4000 rockets were fired towards Israel’s northern region [1].

Dealing with short and medium range indirect fire (such as Katyusha rockets) has always been a great challenge for the Israeli Defense Force (IDF). This type of weapon is mounted on a small truck, hauled by mules or even carried by the operator. These weapons have very low signature and therefore are very hard to detect before they are launched. Furthermore, the rocket operators have adopted a “Shoot and scoot” tactic; immediately following the shooting of a few rockets they hurry away from the scene, often leaving behind the cheap, disposable launcher (which may be no more than a metal tube). Therefore, the response time of the defender must be very short to effectively target the rocket operator.

In recent years U.S. forces are facing similar attacks in Afghanistan and Iraq where insurgent forces fire improvised mortar and rockets at both remote military outposts and major urban areas (e.g. the “Green zone” in Bagdad) causing both casualties and disorder.

In this thesis, we study the problem of counter-rocket tactics by developing a probability model that captures key factors affecting this combat situation. In particular, we propose a new tactic and examine it using the probability model.

The model developed in this thesis is positioned within the rich research area of missile defense. In their book [2] Eckler and Burr discuss a series of models exploring offense and defense strategies in allocating ammunition for single and multiple targets. Soland [3] explores defense tactics that try to minimize the fraction of a target destroyed by the attack when the defender has shoot-look-shoot capability and can execute several sequential engagements to intercept the attack. In this thesis we deal with a special case of missile defense where first, the defender attacks the launching platform or its operator rather than the incoming missiles; and second, the defender has to tradeoff timeliness (i.e. the target is time sensitive) with accuracy. We introduce a new tactic (which may call for a new weapon as well) that tries to mitigate the defender's dilemma "wait or shoot" by using information about the attacker's location which becomes available after the defender has counter fired.

Some similarities can be drawn to Ravid [4] where two alternatives of defense against attacking aircrafts are compared: early engagement before Bomb-Release-Line (BRL) versus engagement with higher kill probability After BRL. Another similar work is by Sweat [5] who models a duel scenario where two combatants approach each other. The fire of each combatant becomes more accurate as they get closer to each other. Both combatants must decide when to shoot. In our case however only the defender has such a decision to make where as the attacker's strategy is predetermined and unaffected by the actions of the defender.

The thesis is organized as follows. In Chapter II we provide the reader with background; we describe the current counter rocket tactic and the suggested new tactic; and finally we describe the model scenario. In Chapter III, we develop the general analytic model and its variation under different assumptions; we present the results and discuss the defenders dilemma "wait or launch" under several assumptions. In Chapter IV, we explore how false positive detections affect our proposed tactics. For this purpose, we develop a simulation. We present the results and perform sensitivity analysis for some of our assumptions. Finally, in Chapter V, we present a summary and conclusions.

II. THE COMBAT SITUATION AND ENGAGEMENT TACTICS

In this chapter, we provide background and introduce the reader to the counter rocket/artillery combat situation and the current tactic employed. We discuss the disadvantages of the current tactic and suggest a new tactic to mitigate these disadvantages. Finally, we describe the scenario we are about to model and introduce our Measures of Evaluation (MOEs).

A. CURRENT COMBAT SITUATION AND TACTICS

Typically, to counter rocket, artillery or mortar fire (henceforth called “rockets”), a ground based sensor (e.g., radar) is assigned to continuously scan a “hot” sector of the battlefield, detect enemy rockets, and locate the positions of the hostile rocket launchers. To allow the use of high precision weapons against the rocket launchers, and in order to reduce collateral damage, the defender’s ground based sensor attempts to gather as much information as possible about the location of the launchers before the defender retaliates.

Specifically, following detection, the ground sensor will try to track the trajectory of a rocket for as long as possible until it must stop either because, it is assigned to track a new rocket or, because the trajectory of the current rocket is too high to be “seen” by the ground sensor. The estimated trajectories of the rockets are recorded and averaged and, based on these averages, the launcher location is estimated. The decision to open counter-fire aimed at the launcher may depend on the accuracy of the location estimation. The larger the number of rockets observed by the ground sensor, the larger the sample size of the estimated trajectories and thus the higher the accuracy of the launcher position. However, while this tactic of “wait-and-observe” increases the accuracy of the location estimate, it consumes valuable time during which the operators of the enemy’s launchers may escape and thus render the counter-fire useless. This tactical situation, which is described in the introduction, represents situations such as countering mobile artillery or short range rocket fire by insurgency/terrorist attack.

B. SUGGESTED TACTIC AND WEAPON

To mitigate the possibility that the counter-attack will be executed too late, we propose a new tactic, which is described next. This tactic may require a new type of weapon.

Consider a single rocket launcher. Following the first detected rocket in the attacker's salvo, the defender's ground sensor obtains an initial rough estimate of the launcher's location and immediately launches a precision guided missile (PGM) directed towards that estimated location of the attacker's launcher. While the prompt response will save precious time, this is not enough; accuracy is also needed for effective counter-fire. The accuracy may be achieved by updating the location estimates of the attacker, while the PGM is airborne, based on detection of subsequent rockets in the salvo. There are two possible methods to create and utilize these updates:

1. The ground sensor observes the trajectories of subsequent rockets and generates improved updates of the location estimates of the enemy's launcher that are transmitted to the missile. Based on these updated estimates the trajectory of the defender's PGM may be updated in-flight.
2. The missile is equipped with an EO/IR sensor which can detect the launches of subsequent rockets in the salvo while airborne, and based on these cues it autonomously updates its trajectory.

Although the ground sensor may have more energy and resources than a missile sensor, it is possible that Method 2 may allow for higher accuracy than achieved by the fixed ground sensor in Method 1 because, as the missile approaches the attacker's location, the range gets shorter and thus the location estimates becomes more and more accurate. If these in-flight updates, either Method 1 or Method 2, are feasible, they may compensate for the disadvantage of launching the missile as early as possible based only on a rough estimate of the attacker's location.

In this thesis, we study under what technical and operational conditions this tactic is superior to the current one where the defender waits and gathers as much information as possible about the location of the launchers before launching the PGM.

C. SCENARIO

We consider the following situation. An attacker fires a salvo of several rockets at a defender from a mobile, possibly improvised, rocket launcher. The defender uses a ground sensor to detect the rocket launches. We assume that the ground sensor may only detect the rocket at the moment of launch; it cannot detect a rocket once airborne and it does not gather any more information from the rocket's trajectory.

Once a rocket launch has been detected by the ground sensor, the defender immediately launches a missile aimed at the attacker. We assume that the defender launches at most one missile per rocket salvo. The attacker stays in position at the launching location until he has fired the last rocket in the salvo. Soon after the last rocket of the salvo is fired, the attacker (launch platform or just the operator of the weapon) disappears from the launching site and becomes invulnerable to the defender's missile. Since it takes some time for the missile to reach its destination, it is possible for the missile to reach the attacker's launching location after the attacker has escaped, in which case the defender has failed his objective to kill the attacker.

If the missile is launched in such a time that allows the missile to reach the attacker's launching location while the attacker is there, then the attacker may be killed with some probability. The (conditional) kill probability of the missile may or may not depend on how early it was launched during the salvo. If the missile is "dumb," meaning that it does not have any in-flight guiding mechanism that can improve its accuracy based on new information obtained during its flight, then this probability is fixed; more rocket detections will have no effect on the accuracy of the missile. If the missile is "smart", meaning that it does have in-flight guiding mechanism, it may use information while airborne, gathered either by the ground sensor (Method 1 above) or by an onboard sensor (Method 2). In that "smart" case, some of the residual rockets in the salvo may be detected, which will update the missile's trajectory and improve its effectiveness (higher probability of kill).

In the absence of false positive detections, there is no doubt that the suggested tactic will improve the probability of kill for a “smart” missile, which inevitably must be more sophisticated and expensive weapon. However, every sensor has some rate of false positive detections. Implementing the tactic as suggested above, where the defender fires a missile once a rocket has been detected by the sensor, will most likely lead to waste of missiles. In an extreme scenario, where the attacker is not firing at all (a cease fire) the rate of wasted missiles equals the rate of false detections. Besides the cost of wasted munitions, firing needlessly will increase collateral damage. We therefore introduce false detections to the model in Chapter 4 and accordingly suggest a missile launch decision mechanism to reduce the rate of unwanted missile launches.

Our major measures of effectiveness in this thesis are therefore, the unconditional probability of killing the attacker, $P_{success}$; and the probability of a false salvo declaration (and missile launch) or rate of false salvo declarations.

III. THE ANALYTIC MODEL - NO FALSE POSITIVES DETECTIONS

In this chapter, our main assumption is that the ground sensor has no false positive detections. This simplifying assumption allows us to use analytic tools and explore our MOEs through their explicit expressions.

Notation Definitions and General Assumptions

We make the following assumptions and notation:

- The ground sensor has no false positive detections (we shall relax this assumption in chapter 4).
- Number of rockets N in a salvo is fixed.
- The number of *residual rockets* in the salvo after the k^{th} rocket is $N-k$.
- The *inter-firing* times T_f between rockets in a salvo, are iid with cdf $F(t_f)$ and pdf $f(t_f)$.
- The *escape time* T_e is the time that passes from the firing of the last rocket till the moment the attacker disappears. This time is independent of T_f and has cdf $G(t_e)$ and pdf $g(t_e)$.
- The missile flight time τ_m is fixed.
- All detections occur at the time of the rockets' launches.
- The ground sensor detects a launch with probability α independently from rocket to rocket.
- The defender launches a missile immediately following the first detected rocket launch.
- No more than one missile is launched per salvo.

- A *timely hit* occurs when the missile reaches its destination before the attacker has escaped.
- The missile probability of kill, given the target is present at time of impact is P_{kill} (and zero otherwise).

A. GROUND SENSOR AND “DUMB” MISSILE

1. Assumption

In this subsection, we explore the model where the defender’s missile is “dumb”, meaning that once the missile has been launched it can neither gather nor receive from the ground sensor any more information about its target location. Therefore it cannot adjust its trajectory while airborne, and thus cannot enhance its accuracy. In our model this assumption is implicit in the fact that P_{kill} is fixed regardless of the number of residual rockets.

2. Deriving the Model Equation

We wish to compute $P_{success}$ - the probability that the attacker has been killed.

We first look at the distribution of the random variable T_{N-k} – the time left from the detection of the k^{th} rocket till the attacker has escaped.

Since T_{N-k} is the sum of $N-k+1$ random variables: $N-k$ rocket inter-firing times and the escape time, the probability density function of T_{N-k} denoted $h_{N-k}(t_{N-k})$ is the convolution of $(N-k+1)$ density functions, $N-k$ density functions of T_f , the inter-firing times, and one density function of T_e , the escape time.

We get:

$$h_{N-k}(t_{N-k}) = \underbrace{((f * \dots * f))}_{N-k \text{ times}} * g)(t_{N-k}) \quad (0.1)$$

By integrating we may find the corresponding cumulative distribution function

$$H_{N-k}(t_{N-k}) = P\{T_{N-k} \leq t_{N-k}\}$$

The probability of success is therefore given by:

$$P_{success} = \sum_{k=1}^N (1-\alpha)^{k-1} \cdot \alpha \cdot P\{T_{N-k} \geq \tau_m\} \cdot P_{kill} = \sum_{k=1}^N (1-\alpha)^{k-1} \cdot \alpha \cdot [1 - H_{N-k}(\tau_m)] \cdot P_{kill} \quad (0.2)$$

3. Deriving $H_{N-k}(t_{N-k})$

To facilitate carrying out the convolutions in the following derivation I will use the Laplace transform and its following properties.

- Given a non negative function $f(x)$, its Laplace transform is defined as:

$$\varphi(s) = L(f) = \int_0^{\infty} e^{-s \cdot x} f(x) dx \quad (0.3)$$

- The Laplace transform of a convolution of two functions is the multiplication of their Laplace transforms:

$$L(f * g) = L(f) \cdot L(g) \quad (0.4)$$

$$f * g = L^{-1}\{L(f) \cdot L(g)\} \quad (0.5)$$

- The Laplace transform of the integration operator:

$$L^{-1}\left\{\frac{1}{s} L(f)\right\} = \int_0^t f(t') dt' \quad (0.6)$$

- The Laplace transform of an exponential factor:

$$L^{-1}\{L(f) \cdot (s - \alpha)\} = e^{-\alpha t} f(t) \quad (0.7)$$

- The Laplace transform of a time shift:

$$L^{-1}\{L(f) \cdot e^{-\alpha t}\} = f(t - \alpha) \cdot U(t - \alpha) \quad (0.8)$$

Where $U(t)$ is the unit step function.

3.1 First Case - Uniform Distributions

In this case we assume both the inter-firing times and the escape time have Uniform distributions.

We denote the mean inter-firing time as μ_f and the mean time to escape as μ_e .

The density functions and their respective Laplace transforms are then given by:

$$f(t_f) = \begin{cases} \frac{1}{2a} & 0 \leq |t_f - \mu_f| \leq a \\ 0 & \text{o.w.} \end{cases} \quad (0.9)$$

$$\varphi_f(s) = L(f) = \frac{1}{2as} (e^{-(\mu_f-a)s} - e^{-(\mu_f+a)s}) = \frac{1}{2as} e^{-(\mu_f-a)s} (1 - e^{-2as})$$

$$g(t_e) = \begin{cases} \frac{1}{2b} & 0 \leq |t_e - \mu_e| \leq b \\ 0 & \text{o.w.} \end{cases} \quad (0.10)$$

$$\varphi_g(s) = L(g) = \frac{1}{2bs} (e^{-(\mu_e-b)s} - e^{-(\mu_e+b)s}) = \frac{1}{2bs} e^{-(\mu_e-b)s} (1 - e^{-2bs})$$

Substituting (0.9) and (0.10) into (0.1) and using the relationship in (0.4) we get:

$$\begin{aligned} L(h_{N-k}) &= \varphi_f(s)^{(N-k)} \cdot \varphi_g(s) = \\ &= \left[\frac{1}{2as} e^{-(\mu_f-a)s} (1 - e^{-2as}) \right]^{(N-k)} \cdot \frac{1}{2bs} e^{-(\mu_e-b)s} (1 - e^{-2bs}) \end{aligned} \quad (0.11)$$

We expand the expression using Newton's binomial formula:

$$\begin{aligned} L(h_{N-k}) &= \frac{1}{(2a)^{(N-k)} s^{(N-k)}} e^{-(\mu_f-a)(N-k)s} \cdot \\ &\cdot \sum_{m=0}^{N-k} (-1)^m \binom{N-k}{m} e^{-2ams} \cdot \frac{1}{2bs} [e^{-(\mu_e-b)s} - e^{-(\mu_e+b)s}] \end{aligned} \quad (0.12)$$

Rearranging we get:

$$\begin{aligned} L(h_{N-k}) &= \left\{ \frac{1}{(2a)^{(N-k)} \cdot 2b} \right\} \cdot \left\{ \frac{1}{s^{(N-k+1)}} \right\} \cdot \\ &\cdot \left\{ \sum_{m=0}^{N-k} (-1)^m \binom{N-k}{m} [e^{-[(\mu_f-a)(N-k)+2am+(\mu_e-b)]s} - e^{-[(\mu_f-a)(N-k)+2am+(\mu_e+b)]s}] \right\} \end{aligned} \quad (0.13)$$

We notice that (0.13) is composed of three parts (separated by parentheses), the first part is some constant independent of s, the second part is $\frac{1}{s^{(N-k+1)}}$, and the third part is a sum of exponents dependent on s.

It can be shown that:
$$L^{-1}\left(\frac{1}{s^{(N-k+1)}}\right) = \frac{t^{(N-k)}}{(N-k)!}$$

Recalling from relationship (0.8) that exponents in the s domain are translations in the time domain we get the final result:

$$h_{N-k}(t) = \frac{1}{(2a)^{(N-k)} \cdot 2b} \sum_{m=0}^{N-k} (-1)^m \binom{N-k}{m} \cdot \frac{1}{(N-k)!} \cdot [(t - \beta_-^m)^{(N-k)} \cdot U(t - \beta_-^m) - (t - \beta_+^m)^{(N-k)} \cdot U(t - \beta_+^m)] \quad (0.14)$$

Where:

$$\beta_-^m = (\mu_f - a)(N - k) + 2am + (\mu_e - b)$$

$$\beta_+^m = (\mu_f - a)(N - k) + 2am + (\mu_e + b)$$

We can very easily carry out the integration and get:

$$H_{N-k}(t) = \frac{1}{(2a)^{(N-k)} \cdot 2b} \sum_{m=0}^{N-k} (-1)^m \binom{N-k}{m} \cdot \frac{1}{(N-k+1)!} \cdot [(t - \beta_-^m)^{(N-k+1)} \cdot U(t - \beta_-^m) - (t - \beta_+^m)^{(N-k+1)} \cdot U(t - \beta_+^m)] \quad (0.15)$$

3.2 Second Case – Normal Distributions

In this case we assume both the inter-firing times and the escape time have normal distributions. We denote the mean inter-firing time as μ_f with variance σ_f^2 and the mean time to escape as μ_e with variance σ_e^2 . In this case T_{N-k} has a normal distribution with mean $\mu_{N-k} = (N - k) \cdot \mu_f + \mu_e$ and variance $\sigma_{N-k}^2 = (N - k) \cdot \sigma_f^2 + \sigma_e^2$.

We note that a Normal random variable may assume negative values which are not appropriate in the case of time. However, it can be easily shown that for the scenario explored in this paper, the negative tail of the normal distribution is insignificant and truncating it will not have significant effect on the results.

3.3 Third Case - Exponential Distributions

In this case, we assume both the inter-firing times and the escape time have exponential distributions.

We denote the mean inter-firing time as $1/\lambda_f$ and the mean time to escape as $1/\lambda_e$.

The density functions and their respective Laplace transforms are then given by:

$$f(t_f) = \lambda_f e^{-\lambda_f t} ; \varphi_f(s) = L(f) = \frac{\lambda_f}{\lambda_f + s} \quad (0.16)$$

$$g(t_e) = \lambda_e e^{-\lambda_e t} ; \varphi_g(s) = L(g) = \frac{\lambda_e}{\lambda_e + s} \quad (0.17)$$

Substituting (0.16) and (0.17) into (0.1) and using the relationship in (0.4) we get:

$$L(h_{N-k}) = \varphi_f(s)^{(N-k)} \cdot \varphi_g(s) = \frac{\lambda_f^{(N-k)}}{(\lambda_f + s)^{(N-k)}} \cdot \frac{\lambda_e}{\lambda_e + s} \quad (0.18)$$

We define: $s' = \lambda_e + s$ and substitute into 11)

$$L(h_{N-k}) = \frac{\lambda_f^{(N-k)} \cdot \lambda_e}{(\lambda_f - \lambda_e + s')^{(N-k)}} \cdot \frac{1}{s'} = \frac{\lambda_f^{(N-k)} \cdot \lambda_e}{(\lambda_f - \lambda_e)^{(N-k)}} \cdot \frac{1}{s'} \cdot \frac{(\lambda_f - \lambda_e)^{(N-k)}}{(\lambda_f - \lambda_e + s')^{(N-k)}} =$$

$$\left\{ \frac{\lambda_f^{(N-k)} \cdot \lambda_e}{(\lambda')^{(N-k)}} \right\} \cdot \left\{ \frac{1}{s'} \right\} \cdot \left\{ \frac{(\lambda')^{(N-k)}}{(\lambda' + s')^{(N-k)}} \right\} \quad (0.19)$$

We notice that (0.19) is the multiplication of three expressions (separated by parentheses), the first one being independent of s' , the second one is just the inverse of s' and the third we recognize to be the Laplace transform of the Erlang density function with parameters $N-k$, and $\lambda' = \lambda_f - \lambda_e$.

We recall the relationship in (0.7) and so we get the final result.

$$h_{N-k}(t) = e^{-\lambda_e t} \frac{\lambda_f^{(N-k)} \cdot \lambda_e}{(\lambda_f - \lambda_e)^{(N-k)}} \left[1 - \sum_{m=0}^{N-k-1} e^{-(\lambda_f - \lambda_e)t} \frac{((\lambda_f - \lambda_e)t)^m}{m!} \right] \quad (0.20)$$

The exponent at the beginning of (0.20) is the result of the substitution we made in (0.18) and the relationship in (0.7).

4. Analysis

Now that we have an expression for $H_{N-k}(t_{N-k})$ we can calculate the probability for a timely hit and therefore – by factor multiplication – the probability of killing the attacker.

We would like to explore how $P_{success}$ is affected by variations in the technological (e.g. missile speed, ground sensor's probability of rocket detection, missile lethality) and operational (e.g. defender attacker distance, rockets rate of fire) parameters.

Recall the expression for $P_{success}$.

$$P_{success} = \sum_{k=1}^N (1-\alpha)^{k-1} \cdot \alpha \cdot P\{T_{N-k} \geq \tau_m\} \cdot P_{kill} \quad (3.2)$$

Next we analyze the problem with respect to the three aforementioned cases:, Uniform, Normal and Exponential distributions. In all three cases we make the same assumptions as described in the introduction to Chapter 3 and in section 3.A.1. We analyze the effect of missile flying time on the probability of success. Recall that for the “dumb” missile $P_{success}$ is proportional to P_{kill} therefore we can focus only on the probability of a timely hit.

We first substitute our results for $H_{N-k}(t_{N-k})$ composed of uniform distributions from subsection A.3.1.

Uniform Distributions

The scenario:

There are $N = 5$ rockets in the salvo. The attacker is using some kind of short range mortar similar to the U.S. Army's M224. The inter-firing time is uniformly distributed between 4.5 to 5.5 seconds (reasonable for this kind of weapon see [6]). The attacker is well prepared for escape prior to firing the salvo and therefore the time to escape is uniformly distributed between 14 to 16 seconds; $\alpha = 0.7$; $P_{kill} = 1$

Figure 1. Probability of success for different missile flight times*

* Flight times are in seconds

Figure 1 presents the probability of success for different missile flight times. We see that the probability of success is a monotone non-increasing function of the missile flight time. This comes as no great surprise since we know the longer it takes the missile to reach the target the higher the chances are that the target will escape before the missile hits the ground.

We notice that the decrease is occurring in 5 steps. The last drop to zero occurs when the missile flight time is about 35 seconds.

We note that the average time the enemy is in position after the first rocket is fired is given by: $(N - 1) \cdot \mu_f + \mu_e = 35$ seconds.

To understand the behavior of the probability of success as shown in the curve of Figure 1, let's explore the probability for a timely hit when there are $N-k$ residual rockets, given by $P\{T_{N-k} \geq \tau_m\} = 1 - H_{N-k}(\tau_m)$.

The following Figure presents $P\{T_{N-k} \geq \tau_m\}$ for different numbers of residual rockets $N-k$, and missile flight time τ_m . The scenario parameters are as in Figure 1

Figure 2. Probability of a timely hit for different missile flight times (in seconds) and number of residual rockets*

* To properly read this figure, print in color.

We notice that the probability of a timely hit given the number of rockets left in the salvo is a sharp step function, in particular for a small number of residual rockets. The drop moves in the positive direction of the τ_m axis for increasing number of residual rockets.

This makes sense because each rocket left in the salvo increases the average time till the target escapes and allows more time for the missile to reach its target. We see that each one of the curves is indeed shifted by about 5 seconds which corresponds to the mean inter-firing time of the rockets.

We go back now to analyze the behavior of the probability of success in Figure 1. Recall from Equation (0.2) that the probability of success is expressed by a sum of arguments, each one containing the probability for a timely hit given a different number of residual rockets. Consider now the region in Figure 1 for values greater than 35 seconds. Looking in the corresponding region in Figure 2 we see that the probability for a timely hit is zero for any possible number of residual rockets (0 to $N-1$) in this scenario. When the missile flight time is very long, even detection of the very first rocket (leaving 4 more rockets in the salvo) does not leave enough time for the missile to reach the target in time.

Now consider the region where τ_m is between about 30 and 35 seconds. According to our scenario the average time between the first rocket launch in the salvo and the moment the attacker escapes is 35 seconds. On average there are 30 seconds between the second rocket launch in the salvo and the moment the attacker escapes, and so on. Notice in Figure 2 that for this $[30,35]$ region of τ_m the probability for a timely hit is non zero if there are 4 rockets left in the salvo, and zero or close to zero if there are less than 4 rockets left in the salvo, meaning that the first rocket must be detected in order to have a significant probability of timely hit. In Figure 1, we see a step up in the probability of success when $\tau_m < 35$ seconds. If we decrease the missile flight time further we enter a region in Figure 2 where the probability of timely hit is significantly greater than zero if the number of rockets left in the salvo is at least 3. This means that in the expression for the probability of success (0.2) two of the arguments in the sum are now non-zero. This is why we see another step up in the probability of success as we decrease τ_m .

As discussed above, the probability of success decreases in steps when increasing the missile flight time. However, we notice that the size of each step is not the same; the last decrement (when τ_m increases above 35 sec) being the largest.

To understand why this happens we go back to the expression of the probability of success in Eq.(0.2). We notice that the arguments of the sum are multiplied by a discrete function of k , $d(k) = (1 - \alpha)^{k-1} \cdot \alpha \cdot P_{kill}$. Since α is between 0 and 1 $d(k)$ is monotone increasing with the number of residual rockets. $d(k)$ controls the step size of the curve in Figure 1(probability of success), we can now see why the returns for decreasing the missile flight time are diminishing.

The initial increase in the probability of success (when the missile flight time is just small enough to give some chance of success), is given by $d(k)$ for the case when $k=1$, which gives: $d(1) = \alpha \cdot P_{kill}$. So, if reducing the missile flight time is difficult, and we want to maximize the initial jump in the probability of success, we should increase α as much as possible.

At the heart of this qualitative behavior of step decreases in the probability of success seen in Figure 1, is the fact that we chose time parameters (inter-firing and escape) with relatively small variances. These small variances lead to uniform cdf close to a step function. The uniform cumulative distribution becomes close to a step function whenever we reduce the range between its two parameters relative to their midpoint (mean). This occurs because the pdf will become close to an impulse function and thus the cdf will become close to a step function. This in turn makes the distribution $H_{N-k}(t_{N-k})$ resemble a step function.

When we increase the range of the distribution, we increase the variance relative to the mean of the underlying distributions and we get less steep CDFs. This will change the discrete jump nature of the curve we see in Figure 1 and make the probability of success plot "smoother".

Figure 3 presents the probability of a timely hit for the uniform distribution case with greater variability. Figure 4 presents the resulting probability of successes.

The scenario is:

There are $N = 5$ rockets in the salvo as before. The attacker uses the same weapon however he fires at a less regular rate and the inter-firing time is uniformly distributed

between 4 to 6 seconds. The time to escape is uniformly distributed between 10 to 20 seconds. Notice that the means of the underlying distributions are still 5 and 15 seconds, respectively, as before. $\alpha = 0.7$; $P_{kill} = 1$

Figure 3. Probability of a timely hit for different missile flight times (in seconds) and number of residual rockets (increased variability) *

* To properly read this figure, print in color.

Figure 4. Probability of success for different missile flight times (in seconds)
(increased variability)

Exploring the case of normal distributions gives similar results to the uniform case. Therefore we move directly to the exponential case. Results for the normal case are presented in appendix A.

Exponential Distributions

An interesting case is the case where both the escape time and the inter-firing times are exponential random variables. In this case, the mean and the variance are coupled and the ratio between the mean and the standard deviation is always 1. Therefore we never achieve the qualitative behavior of step decreases and always get a smooth curve as in the high variability case above. There is still some effect of diminishing returns, however; it seems the “knee” of the curve is only achieved for a relatively low missile flight time. Another interesting observation is that for the exponential case the

probability of successes is quite high even for very high values of missile flight time. This is again due to the high variability imposed by the exponential distribution because the variance is the square of the mean.

Figure 5 and 0 present the exponential case. The mean times are the same as in Figure 3 and Figure 4

Figure 5. Probability of a timely hit or different missile flight times (in seconds) and number of residual rockets (Exponential case) *

* To properly read this figure, print in color.

Figure 6. Probability of success for different missile flight times (in seconds)
(Exponential case)

5. Tradeoff: Wait or Launch?

Recall that the probability of success depends on two factors: timely hit and accuracy. So far we assumed perfect accuracy and only looked at the defender's attempt to respond as quickly as possible and so increase the probability of timely hit. However, in reality accuracy is not perfect and by waiting and sampling more rockets in the salvo the defender may improve his accuracy at the cost of reducing the probability of timely hit. So the question is *wait* and improve accuracy while reducing the probability of timely hit, or *launch* with lower accuracy but higher probability of timely hit.

Let us now assume that the defender launches the missile after M detections. The missile will be aimed at the average of the M location estimates. The serial number k of the rocket after which the missile is launched has a negative binomial distribution with

parameters M and α . We further assume that the defender's missile has a cookie cutter damage function with lethal radius R :

$$d(r) = \begin{cases} p & r \leq R \\ 0 & \text{o.w.} \end{cases} \quad (0.21)$$

and that the defender's errors of the estimates of attacker's location after each rocket detection are iid circular normal random variables with mean $\mu = 0$ and variance σ^2 . The

average error of M estimates will then have a mean $\mu_M = 0$ and a variance $\sigma_M^2 = \frac{\sigma^2}{M}$. We then get the expression for the probability of kill (see also [7]):

$$P_{kill} = \iint d(r) \cdot \frac{M}{2\pi\sigma^2} e^{-\frac{Mr^2}{2\sigma^2}} r \cdot dr \cdot d\phi = p \cdot (1 - e^{-\frac{MR^2}{2\sigma^2}}) \quad (0.22)$$

We rewrite Eq. (0.2) as follows:

$$P_{success} = \sum_{k=M}^N \frac{(k-1)!}{(M-1)!(k-M)!} \cdot (1-\alpha)^{k-M} \cdot \alpha^M \cdot (1 - H_{N-k}(\tau_m)) \cdot p \cdot (1 - e^{-\frac{MR^2}{2\sigma^2}}) \quad (0.23)$$

0 presents the probability of success for different missile flight times and different M values. The scenario is the same as in Figure 1; that is, uniform inter-firing and escape distributions. We choose: $p = R = \sigma^2 = 1$.

Figure 7. Probability of success for different missile flight times (in seconds) and different M values.*

* To properly read this figure, print in color.

We see that if the defender chooses to shoot as early as possible immediately after the first detection ($M = 1$) then even a slow flying missile, which takes as long as 35 seconds to reach the attacker, may still hit the attacker with probability of ~ 0.15 . For $M > 1$ this probability is 0. However in this case the maximum probability of success is about 0.4 for different defender missile flight times. On the other hand, waiting for the second detection does not allow the defender to use a missile which takes longer than about 32 seconds to reach the target; however the maximum probability of success is about 0.62.

We see that there is a tradeoff between the defender waiting to launch until more than one rocket has been detected and thus improving the probability of kill vs. the defender launching the missile as early as possible and saving valuable time. Waiting too long ($M=5$) is not beneficial because the loss of valuable time overrides the gain in accuracy and the net result is a low probability of success. The dashed black line marks the maximal value over all 5 curves. We see that if the defender has a very fast missile ($\tau_m \leq 15$ sec), the defender should wait for 3 detections before launching the missile. However if the defender has a missile which takes more than about 15 seconds to reach the target but less than 25 seconds, he should wait for only 2 detections, and if the missile takes longer than about 25 seconds the defender should launch his missile immediately after the first detection.

There is another element influencing the probability of success beside the probability of timely hit and accuracy. This other element is the probability of *missile launch*. Notice that in our formulation for every value of M there is some chance that no more than $M-1$ rockets will be detected, in which case the missile is not launched at all. Consider the region in 0 where $\tau_m = 0$. Obviously a timely hit is guaranteed in this case. One might expect the curves to be ordered such that the most “accurate” missile ($M = 5$) will be on top, and the least “accurate” missile ($M = 1$) at the bottom. However we see that the curve with the lowest probability of success is the one where $M = 5$ and the missile is the most accurate. We get this result because the event *5 out of 5 rockets detected* is less likely than for instance than the event *1 out of 5 rockets detected*. Figure 8 presents the case where the probability of rocket detection is 1. The rest of the scenario is just as in 0 Notice when $\tau_m = 0$ the curves are ordered by M from top to bottom. We notice that in this case the defender’s best policy changes, and for low values of τ_m the defender should wait for 4 or even 5 detected rockets before launching his missile.

Figure 8. Probability of success for different missile flight times (in seconds) and different M values.* (Perfect detection)

* To properly read this figure, print in color.

0 presents the probability of success for different missile flight times and different M values for the exponential case, that is exponential inter-firing and escape distributions. The mean inter-firing time and escape time are 5 and 15 seconds respectively. We choose: $p = R = \sigma^2 = 1$

Figure 9. Probability of success for different missile flight times (in seconds) and different M values.* (Exponential case)

* To properly read this figure, print in color.

Just as in Figure 6, we note that the curves in the exponential case are smoother and with a longer “tail” than in the uniform case. This is due to the greater variability in the exponential case and to the pdf’s shape. Comparing 0 with 0, we find great similarity between the two figures. We find the same curves intersect with each other in both figures (for instance $M = 1$ intersect $M = 2, 3 \& 4$ in both figures), a lower M allows the defender to use a slower missile and so on. In both cases we see that given a very fast missile the best policy of the defender is to launch after $M = 3$ detected rockets; for a slower missile the defender should launch after $M = 2$ detected rockets; and for a very slow missile the defender should launch at $M = 1$. However, in the exponential case the region of τ_m where $M = 2$ is the best policy extends from $\tau_m \sim 5$ to $\tau_m \sim 40$. Even beyond $\tau_m \sim 40$ where $M = 1$ is the best option for the defender, the difference in the

probability of success between $M = 1$ and $M = 2$ seems insignificant. It would seem then that in the exponential case, if there is some ambiguity regarding τ_m the defender's "best bet" would be to launch after $M = 2$ detected rockets.

B. GROUND SENSOR AND "SMART" MISSILE

1. Assumptions

So far, we have assumed that once the missile has been launched it cannot get any more information about the location of the target. In our model this assumption was implicit in the fact that P_{kill} was fixed regardless of the number of residual rockets or the value of τ_m .

We now assume that the defender has a "smart" missile, meaning that the missile has an in-flight guiding mechanism. The "smart" missile may use new information gathered while it is airborne. This new information may be gathered either by the ground sensor or by an onboard sensor. With this capability, some of the residual rockets in the salvo may be detected and be used to improve the estimation of the target location. The improved estimate may enhance the accuracy of the missile and result in higher value of P_{kill} .

Recall that for the "dumb" missile P_{kill} is fixed regardless of the number of rockets that are launched during the missile's flight. The question now is what will be the behavior of P_{kill} for the "smart" missile.

First, we notice that P_{kill} for the "smart" missile is not smaller than P_{kill} for the "dumb" missile. This is true because the "dumb" missile may be considered as a special case of the "smart" missile. In this special case no new information is gathered (i.e. the sensor providing the new in-flight information is very poor).

Second, we note that P_{kill} must be monotone non-decreasing in the number of residual rockets. The larger the number of residual rockets, the more opportunities there are to obtain additional observations for estimating the target location and thus improve

the trajectory of the defender's missile and enhance its accuracy and effectiveness. We therefore conclude that $P_{kill}(N-k)$ is a monotone non-decreasing function of $N-k$, the number of residual rockets.

Finally, we note that P_{kill} must also be a monotone non-decreasing function of τ_m . Information gathered after the missile has reached its target is lost and cannot change the missile's trajectory. Therefore only rockets launched during the missile's flight can help improve its effectiveness. The longer τ_m the more opportunities there are for detecting residual rockets.

To capture the full picture we should consider the probability of kill to be a function of both the number of residual rockets and of the missile flight time. However finding an analytically tractable closed form expression for $P_{kill}(N-k, \tau_m)$ is difficult (in most cases); we therefore adopt a different approach, using a simulation, to explore our model. The simulation is described in detail in Chapter IV.

2. Ground Sensor Guided "Smart" Missile (Method 1)

We first explore the case where the "smart" missile receives new information gathered by the ground sensor. Following the same arguments as in section 3.A.5 we find an expression for the probability of kill similar to the one in Eq. (0.22). However, now we consider not only the number of rockets detected prior to the defender's missile launch but also the *number L of rockets detected out of V rockets fired while the missile was airborne*. We obtain the following expression:

$$P_{kill} = p \cdot \left(1 - e^{-\frac{(M+L)R^2}{2\sigma^2}}\right) \quad (0.24)$$

We revise (0.23) and obtain the following expression:

$$P_{success} = \sum_{k=M}^N \binom{k-1}{M-1} \cdot (1-\alpha)^{k-M} \cdot \alpha^M \cdot (1-H_{N-k}(\tau_m)) \cdot \sum_{v=0}^{N-k} P\{V=v | N-k, \tau_m\} \sum_{L=0}^v \binom{v}{L} \cdot (1-\alpha)^{v-L} \cdot \alpha^L \cdot p \cdot \left(1 - e^{-\frac{(M+L)R^2}{2\sigma^2}}\right) \quad (0.25)$$

Finding a general expression for $P\{V=v | N-k, \tau_m\}$ when the underlying distribution are Uniform, is quite difficult and so we will use the simulation as mentioned above.

Let us look first at the case of the smart missile launched after $M = 1$ detected rocket. Figure 10 presents the estimated probability of success for a ground sensor guided “smart” missile, launched after $M = 1$ detected rocket. Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos. The results for the “dumb” missile we have presented in section 3.A.5 are also presented here. The scenario is the same as in Figure 1 (Uniform interfering and escape distributions). We assume $p = R = \sigma^2 = 1$.

Figure 10. Simulation estimates* for the Probability of success for a ground sensor guided “smart” missile ($M = 1$) and, calculated Probability of success for the “dumb” missile launched at different number of detections (M) **

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

**To properly read this figure, print in color.

We see that the probability of success is no longer a monotone decreasing function in the missile flight time. Instead, it has a mode, starting at a relatively low level, increasing to a maximal probability of about 0.8 and then dropping to zero.

We recall that in this scenario, the missile has to be in flight to receive any new information after it has been launched, this accounts for the initial increase in the probability of success we see in the figure above. As τ_m increases there is a higher chance that additional rockets will be fired during the missile’s flight; additional

observations increase P_{kill} and finally the probability of success. As the missile flight time increases, eventually the probability of a timely hit decreases; this in turn decreases the probability of success and eventually reduces it to zero.

Notice that the “smart” missile with $M = 1$ is always superior to the “dumb” missile with $M = 1$. This is because it will always have at least as much information as the “dumb” missile when launched immediately after the first detection. The probability of success for the “smart” missile when $M = 1$ drops to zero alongside the probability of success for the “dumb” missile when $M = 1$. When $M = 1$ the “smart” missile is launched as early as possible; its chances for a timely hit are just as good as those of the “dumb” missile fired immediately after the first detection. For values of τ_m lower than about 5, the probability of success using the “smart” missile with $M = 1$ is the same as that for the “dumb” missile with $M = 1$. This makes sense because when τ_m is very small, there is very little chance for another rocket to be detected during the “smart” missile’s flight. The “smart” missile will then be aimed only based on the single rocket detected by the ground sensor prior to the missile launch, the same as in the “dumb” missile case with $M = 1$.

Recall that the maximum of the probability of success for the “dumb” missile over all values of M ($\max_M(P_{success})$), provides us with the best course of action the defender can take using the “dumb” missile. Comparing $P_{success}$ for the “smart” missile with $M = 1$ to $\max_M(P_{success})$ for the “dumb” missile, we see that for high values of τ_m the “smart” missile with $M = 1$ is more effective than the “dumb” missile, regardless the value of M . However below a certain value (about 10 sec) of τ_m it becomes better to use a “dumb” missile launched after $M = 3$ detected rockets, than using the “smart” missile with $M = 1$. In this case the missile is effectively so fast that there is no need to rush and launch it early. It is almost guaranteed that a very fast missile will reach its target in time. However it is less likely that during its short flight more rockets will be launched and detected.

Notice that the peak of the probability of success for the “smart” missile is higher than $\max_M(P_{success})$ for the “dumb” missile. This is because when the defender uses the “dumb” missile, his best course of action utilizes the information from at most 3 rockets (he may choose to use the information of more rockets, but the advantage of more information is lost to the disadvantage of launching too late); however the “smart” missile is launched as early as possible, and if it is in the air long enough it may use the information of possibly up to N rockets.

We see that firing the “smart” missile after $M = 1$ detected rocket is not always better than the “dumb” missile. It is interesting to see what happens if the defender uses the “smart” ground sensor guided missile and waits to launch it after more than $M = 1$ detected rockets. Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos. The following figure presents the simulation results for the probability of success for a ground sensor guided “smart” missile, for different values of M . Also presented is the curve of the best course of action the defender can take using the “dumb” missile we have seen in Figure 7 The scenario is the same as in Figure 1 (Uniform inter-firing and escape distributions). We assume $p = R = \sigma^2 = 1$.

Figure 11. Simulation estimates* for the Probability of success for a ground sensor guided “smart” missile launched at different number of detections (M) **

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

**To properly read this figure, print in color.

Comparing Figure 7 and Figure 11 We see that for any given value of M the “smart” missile is superior to the “dumb” missile. However as M gets higher the difference between using the “smart” vs. the “dumb” missile diminishes. This is because the “smart” missile improves on the “dumb” missile by taking advantage of the opportunities to detect residual rockets while it’s airborne. As M increases there are fewer such opportunities. In fact there is no difference between the “smart” and the “dumb” missile when $M = 5$ since there are no residual rockets for the “smart” missile to draw on. The dash-dot black line marks the maximal value over all 5 curves (for the “smart” missile). This line provides us with the defender best policy using the smart missile. We

see just as with the dumb missile the faster the missile the longer the defender is willing to wait (higher M). The defender should never wait for more than $M = 3$ detected rockets. There is no advantage in using the smart missile when τ_m is very small because there is little chance of detecting an additional rocket launch while the missile is airborne.

We notice that in the Uniform distributions case, just as in section 3.A.5 that the increase and decrease in the probability of success occur in steps due to the low variability of the distributions we chose.

When the underlying distributions are exponential, it is easier to find an explicit expression for equation (0.25). When the inter-firing times are Exponential iid random variables and given k we can say that, $V = \min(N - k, X)$ where $X \sim \text{Poisson}(\lambda_f \tau_m)$. Furthermore $L = \min(N - k, Y)$ where $Y \sim \text{Poisson}(\alpha \cdot \lambda_f \tau_m)$ is a Poisson distribution. We can now rewrite (0.25) and get:

$$P_{\text{success}} = \sum_{k=M}^N \binom{k-1}{M-1} \cdot (1-\alpha)^{k-M} \cdot \alpha^M \cdot (1-H_{N-k}(\tau_m)) \cdot \sum_{l=0}^{N-k} P\{L=l \mid N-k, \tau_m\} \cdot (1 - e^{-\frac{(M+l)R^2}{2\sigma^2}}) \quad (0.26)$$

$$\text{Where: } P\{L=l \mid N-k, \tau_m\} = \begin{cases} \frac{e^{-(\lambda_f \cdot \alpha \cdot \tau_m)} (\lambda_f \cdot \alpha \cdot \tau_m)^l}{l!} & 0 \leq l < N-k \\ 1 - \sum_{i=0}^{N-k-1} P\{L=i \mid N-k, \tau_m\} & l = N-k \end{cases}$$

Figure 12 presents the probability of success for a ground sensor guided “smart” missile, alongside the results for the “dumb” missile we have presented in section 3.A.5. The scenario is Exponential inter-firing and escape distributions with means 5 and 15 seconds respectively. We assume $p = R = \sigma^2 = 1$.

Figure 12. Probability of success for a ground sensor guided “smart” missile and, for the “dumb” missile launched at different number of detections (M)*
(Exponential case)

* To properly read this figure, print in color.

We find great similarity between Figure 11 and Figure 12. The ground sensor guided missile is always superior to the “dumb” missile launched at a given number M of detected rockets. For higher values of M the “smart” missile loses its advantage over the “dumb” missile. However, note that the peak probability of success for the “smart” missile has shifted from to lower values of τ_m . For instance for $M = 1$, the peak probability of success has moved from $\tau_m \sim 23$ secs (for the Uniform case) to $\tau_m \sim 15$ secs (for the Exponential case). The peak itself is lower for the Exponential case (about 0.62) then for the Uniform case (about 0.8). Because the inter-firing time in the Exponential case has greater variability, it may assume higher values than in the uniform case. This

reduces the probability of detecting residual rocket fired while the missile is airborne. The probability of timely hit is lower in the Exponential case than in the Uniform case (see Figure 2 and Figure 5). The net result is a lower peak probability of success than in the Uniform case.

3. Onboard Sensor “Smart” Missile (Method 2)

We now explore the case where the “smart” missile receives new information gathered by an onboard sensor.

The onboard sensor presents us with a new situation. We now have to take into account the improvement in both the probability of rocket detection and the probability of kill as the sensor moves toward the attacker’s location; the shorter the distance between the sensor and the launching site, the higher the detection probability and the accuracy of the target location estimate. We assume that the onboard sensor is able to detect and measure the attacker’s location at any range and it is not limited by its footprint or orientation.

It is well known (see [8],[9]) that both parameters – detection probability and accuracy of location estimate – are related to the signal to noise ratio or the energy reaching the sensor from its target. We denote this energy as E .

We take the general relationship between the probability of detection and E from the Albersheim empiric equation (see [8]). We will therefore use the following relationship:

$$P_d(E) = \frac{C_1 \cdot \exp(E)}{1 + C_1 \cdot \exp(E)} \quad (0.27)$$

Where C_1 is some normalization-factor, and $P_d(E)$ is the probability of rocket detection when the sensor receives energy E from the launching site.

Let us assume that the errors of location estimation are iid circular normal random variables with mean zero and variance $\sigma^2(E)$. In [9] it is shown that the variance is related to E as follows:

$$\sigma^2(E) = \frac{C_2}{E} \quad (0.28)$$

Where C_2 is some normalization-factor. We assume that the sensor will use a simple average to integrate the information from several rocket detections.

If at the time of impact the sensor has detected S rockets, each with energy E_i $i=1\dots S$ then the variance of the averaged location estimation will be given by:

$\sigma_s^2 = \frac{1}{S^2} \sum_i \sigma^2(E_i)$. We have already found the relationship between the probability of kill and the variance of the averaged measurements in (0.22). Substituting σ_s^2 and (0.28) into (0.22) gives us the new expression:

$$\begin{aligned} P_{kill} &= p \cdot (1 - \exp(-\frac{R^2}{2\sigma_s^2})) = p \cdot (1 - \exp(-\frac{S^2 R^2}{2 \sum_i \sigma^2(E_i)})) \\ &= p \cdot (1 - \exp(-\frac{S^2 R^2}{2 \sum_i \frac{C_2}{E_i}})) \end{aligned} \quad (0.29)$$

Finally we note that E is some function of D *the distance between the sensor and the target*. The relationship $E(D) \propto \frac{1}{D^4}$ may be appropriate for an active sensor (e.g. A radar which suffers two-way attenuation losses). A passive sensor might have the relationship $E(D) \propto \frac{1}{D^2}$ (e.g. Electro-optical sensor which suffers one way attenuation losses) The relationship $E(D) \propto \frac{1}{D}$ may represent some other kind of sensor.

Equipped with these expressions we can now use our simulation to explore the case of an onboard sensor. Figure 13 and Figure 13Figure 15 present the single detection probability of kill (based only on the information from one rocket detection from that sensor) and the probability of detection for different types of sensors as a function of their distance from the target. The distance is normalized such that $D=1$ is the distance between the ground sensor and the target. We assume that the onboard sensor is much smaller than the ground sensor (due to limited space on the missile) and therefore is

receiving 10 times less energy than the ground sensor i.e. $E_{onboard\ sensor}(D=1) = \frac{E_{ground\ sensor}}{10}$

. This is why at same distance from the target the ground sensor is more effective than the onboard sensor. The normalization-factors C_1 and C_2 in equations (0.27) and (0.29) respectively are chosen such that: $\sigma^2(E_{ground\ sensor})=1$ and $P_d(E_{ground\ sensor})=0.7$; We assume $p = R = 1$.

Figure 13. Single detection probability of kill for different types of sensors

Figure 14.

Figure 15. Probability of rocket detection for different types of sensors

Figure 16 presents the probability of success as a function of the missile flight time for different types of onboard sensors when $M = 1$. The case of the ground sensor guided missile when $M = 1$ is presented for reference. The scenario is as in Figure 1(Uniform inter-firing and escape distributions). We assume $p = R = \sigma^2(E_{ground\ sensor}) = 1$.

Figure 16. Simulation estimates* for the Probability of success as a function of the missile flight time (in seconds) for different types of sensors ($M = 1$). **

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

** To properly read this figure, print in color.

We notice that for high values of τ_m all types of onboard sensors give lower probability of success than the ground sensor. This is because large τ_m implies that the missile is slow; therefore when the residual rockets are launched the onboard sensor is

more likely to be relatively far away from its destination. Because the sensor is far away from the target the overall information it provides (as determined by the number of residual rockets detected and the measurement errors they have) is less than the information that the ground sensor would have provided. However as τ_m becomes smaller (and the missile is faster), we see that the probability of success for the onboard sensor increases (although not in a monotone fashion) until it goes above the probability of success for the ground sensor guided missile. Finally, as in the case of the ground sensor guided missile, when τ_m is small enough the missile is so fast that no rockets are launched or detected during the missile's flight; the resulting probability of success has the same value as if the missile was "dumb".

We note that the probability of success now has more than one mode. For instance for all onboard sensors, there is a gradual decrease in the probability of success when $5 \leq \tau_m \leq 10$, then around $\tau_m = 10$ there is a sharp increase in the probability of success. As we increase τ_m from 5 to 10, the missile becomes slower; the rockets launched during its flight are detected further away from the missile. For this reason the rockets become harder for the onboard sensor to detect and when detected they provide less information and have a less effect on the probability of kill. However since the inter-firing time is uniform between 4.5 and 5.5 seconds, during a flight time of less than 10 seconds no more than 2 rockets may be launched and detected. As we increase τ_m beyond 10 seconds, the opportunity to detect a third rocket arises; the extra rocket will provide more information which causes a spike in the probability of success. This ripple effect would not have been so distinct had we chosen inter-firing times with a greater range.

For the scenario described above, we see it is not beneficial to use an on-board sensor, unless we have a relatively fast missile.

Figure 17 presents the probability of success as a function of the missile flight time for different types of onboard sensors when $M = 1$, for the Exponential case. The

case of the ground sensor guided missile when $M = 1$ is presented for reference. The scenario is Exponential inter-firing and escape distributions with means 5 and 15 seconds respectively. We assume $p = R = \sigma^2(E_{ground\ sensor}) = 1$.

Figure 17. Simulation estimates* for the Probability of success as a function of the missile flight time (in seconds) for different types of sensors ($M = 1$). ** (Exponential case)

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

**To properly read this figure, print in color.

Notice that in the exponential case, when the onboard sensor receives 10 times less energy than the ground sensor, there is hardly any difference between the probability of success if the missile is guided by the ground sensor or by the “Active” onboard

sensor. The active sensor does do slightly better than the ground sensor for $\tau_m \sim 10$ secs. It seems that in this case investing in the development of an onboard sensor is not beneficial.

Finally, we explore the defender's option to wait for M detected rockets before launching the missile. The next 4 figures present the probability of success for the onboard sensor "smart" missile after different number M of detected rockets, for "Active" and "Passive" sensor. The scenario in 0 and 0 is Uniform distributions as in Figure 1 The scenario in Figure 20 and Figure 21 is Exponential inter-firing and escape time with means 5 seconds and 15 seconds respectively.

Figure 18. Simulation estimates* for the Probability of success as a function of the missile flight time (in seconds) for onboard "Active sensor, for different values of M .** (Uniform case)

**To properly read this figure, print in color

Just as with the “dumb” and the ground sensor guided missile, the defender should never wait for more than $M = 3$ detected rockets in this scenario. The black dotted curve is the “best policy” curve for the onboard sensor. Also plotted for reference are the “best policy” curves for the “dumb” and the ground sensor guided missiles. Note that the passive onboard sensor missile is always inferior to the ground sensor guided missile (under these scenarios). The “Active” onboard sensor missile does a little better than the ground sensor guided missile in the Uniform case, but in the Exponential case there is no distinguishable difference between the two.

IV. THE CASE OF FALSE POSITIVE DETECTIONS - A SIMULATION MODEL

A. INTRODUCING FALSE DETECTIONS

1. Assumptions

In Chapter III, we assumed that the ground based sensor has no false positive detections. In this chapter we explore how false positive detections (henceforth called, in short, *false detections*) affect our proposed tactics.

Generally speaking, every sensor has some false detections, which may be due to processes internal to the sensor, or due to external conditions such as weather or interference caused by other systems. In our model we assume that the times between two consecutive false detections are iid random variables independent of whether a rocket has been fired.

We assume that only the ground sensor may have false detections. The missile's onboard sensor does not have false detections.

We assume that the ground sensor makes a measurement of the attacker's location with circular normal distributed errors and variance σ^2 , even when the detection is false. We make this assumption to simplify the simulation. Obviously, in a real-world situation false detections may reduce the missile's accuracy. However this assumption still makes some sense. In a real situation if the false detection is extremely far away from the attacker's location it will not be associated to the salvo. Furthermore, the simulation does handle the cases when false detections trigger a missile launch while there is no ongoing salvo at all. As in Chapter III, we assume that the defender launches at most one missile per salvo.

2. The Firing Rule (\hat{M}, \hat{T})

In Chapter III, we assume that the defender fires back a missile as soon as he detects a rocket within the salvo. In the presence of false detections, such a policy may lead to unnecessary missile launches whenever a false detection occurs. Such missile

launches are disadvantageous for two reasons. First, they cause waste of missiles, which may be limited or expensive; and second, it may lead to unnecessary collateral damage as missiles may hit innocent targets.

To mitigate the problem of unnecessary missile launches, we introduce a new response policy for the defender. We assume that the defender knows that the attacker fires his rockets in salvos of several rockets at a time. The defender takes advantage of this fact and estimates when a salvo has begun by looking for a series of detections close in time. Following such a cluster of detections, the defender makes a *salvo declaration* and fires a missile in response. Such a policy may reduce the rate of launching missiles unnecessarily since now only false detections which occur in close proximity will lead to a false salvo declaration and unnecessary missile launches.

The firing rule is defined by the pair (\hat{M}, \hat{T}) as follows:

Looking at a sliding window in time of size \hat{T} time units, the defender declares a salvo the moment the sliding window contains at least \hat{M} detections, counting from the last detection accounted for by the previous salvo declaration.

Detections from or before the previous salvo declaration are not counted to reduce the number of salvo declarations during the same salvo.

We define a *positive salvo declaration* as a salvo declaration which is made during a real salvo (from the moment the attacker is in position until he has fired the last rocket).

3. Problem Definition

For \hat{M} large enough and \hat{T} small enough the firing rule may reduce the number of false declarations, however it introduces two new problems. First, the probability of a positive salvo declaration is decreased and second, valuable time may be lost waiting for enough detections to meet the firing rule criteria, thus decreasing the probability of timely detection.

We therefore want to find the firing rule pair (\hat{M}, \hat{T}) which gives the best tradeoff between low false salvo declaration rate and high probability of success.

B. SIMULATION DESCRIPTION

Initial attempts to describe the problem in the presence of false detections analytically did not lead to tractable closed form solutions which lend insights easily. We therefore chose to approach the problem using discrete event simulation.

1. Events Graphs

To write our simulation we have used discrete event simulation (DES) methodology and the SimKit programming toolkit (see [10]). DES simulations maintain a list of scheduled events. Each event may affect system variables, schedule future events or, cancel future events. DES simulations are represented by events graphs. The following figure presents a simple example of a DES event graph.

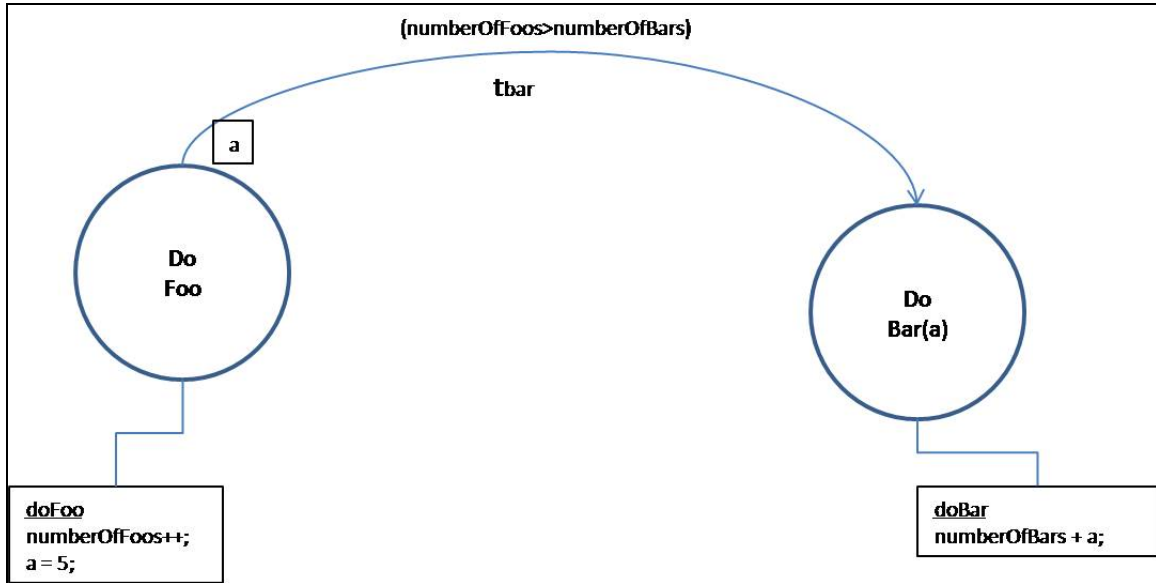

Figure 22. Event graph example

In the simple event graph above, there are two types of events represented by circles: doFoo and doBar(a).

The description of each event is described in a rectangular frame attached to the event by a broken line. doFoo increments the system variable numberOfFoos and

instantiates the variable “a”. doFoo adds “a” (received from its argument) to the system variable numberOfBars. The arc connecting the two events is a scheduling arc. The arc will schedule a doBar(a) event some time units after the execution time of doFoo. The time of scheduling will be determined by the distribution of t_{bar} written next to the arc with no parentheses. If no time distribution is written next to the arc, the scheduled event will be scheduled at the same time as the scheduling event. A doBar(a) event will only be scheduled if the condition numberOfFos is greater than numberOfBars, is met. The arc conditioning is written in parentheses next to the scheduling arc. the event doFoo passes the variable “a” to the event “doBar(a), written in rectangular frame next to the scheduling arc.

For further reading on SimKit and DES see [10].

2. The Simulation Model

The following two figures present our DES event graph. Because of its size, the event graph is divided into two figures, the events marked in red are common to both figures.

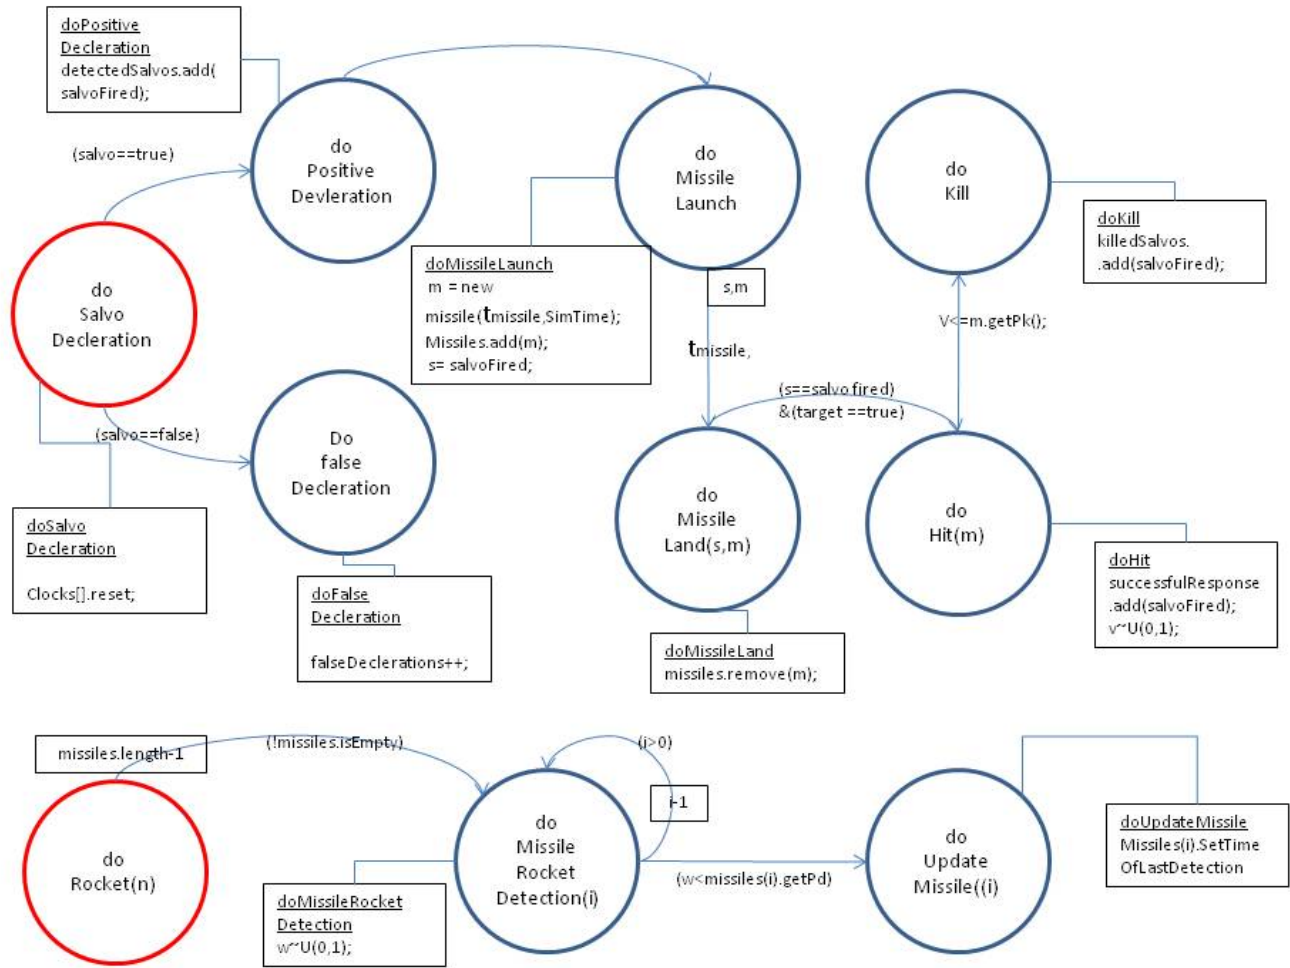

Figure 24. Simulation event graph part B

C. ANALYSIS

1. Positive Salvo Declaration as a Function of the Firing Rule (\hat{M}, \hat{T})

Our MOE is the proportion of positive salvo declarations among the total number of salvos. This MOE estimates the *sensitivity* of our firing rule – the conditional probability of detecting a salvo on time. We call this MOE the *probability of positive salvo declaration*.

The scenario parameters are:

The missile is “Dumb”. There are $N = 5$ rockets in the salvo. The inter-firing time is uniformly distributed between 4.5 to 5.5 seconds. The time to escape is uniformly distributed between 14 to 16 seconds; The probability of rocket detection is $\alpha = 0.7$; to find the conditional probability of kill we use a cookie cutter damage function with parameters $p = R^2 = 1$. We assume the location estimate errors are iid circular normal r.v. with variance $\sigma^2 = 1$. The time between salvos, and the time between false detections are exponentially distributed with mean 7200 seconds (2 hours), and 900 seconds (15 min) respectively. The missile flight time $\tau_m = 20$ seconds is fixed.

Figure 25 presents the probability of positive salvo declaration for different firing rules.

Figure 25. Simulation estimates* of the Probability of positive salvo declaration vs. \hat{T} (in seconds) for different values of \hat{M} **

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

**To properly read this figure, print in color

First, we notice that the probability of positive salvo declaration is increasing with \hat{T} and decreasing with \hat{M} . This is the expected result; as we increase \hat{M} and reduce \hat{T} we make our firing rule tighter. Take for instance an extreme case such as $(\hat{M} = 5, \hat{T} = 0)$. This is the tightest firing rule in Figure 25, and we see the probability of positive salvo declaration is zero. On the other hand, $(\hat{M} = 2, \hat{T} = 40)$ is almost the least tight firing rule in the figure. We see the probability of positive salvo declaration is almost one. When $(\hat{M} = 1)$, the probability of positive salvo declaration is of course one.

Finally, we observe that for a given value of \hat{M} increasing \hat{T} indefinitely (supposedly making the firing rule infinitely lenient), does not lead to positive salvo declaration probability of one. Instead the probability increases with \hat{T} and then stays fixed on a certain value. This phenomenon is due to the fact that in counting detections for the next salvo declaration, we discard detections used for previous salvo declarations. This is equivalent to saying that detections that generate one salvo declaration may not overlap with detections generating the next salvo declaration. As we increase \hat{T} we do initially make the firing rule less demanding; however at a certain point it becomes more and more likely that the time window will include detections from a set that resulted in a previous salvo declaration. From this point on increasing \hat{T} will not make any difference since any detection further back in time is ignored when counting detections for the next salvo declaration. The rate of positive salvo declarations will then become fixed regardless of any increase of \hat{T} . This in turn leads to a fixed probability of positive salvo declarations.

2. False Salvo Declaration as a Function of the Firing Rule (\hat{M}, \hat{T})

The MOE for the false declarations is the ratio between the number of false salvo declarations and the number of total salvo declarations (including duplicate positive declarations of the same salvo). We call this MOE the *false declaration proportion* (FDP). Another MOE is the *false declarations rate* (FDR) – the number of false declarations per unit time (FDR). Figure 26 and Figure 27 present the simulation estimates for the FDP and the overall rate of false salvo declarations.

The scenario parameters are as in 0

Figure 26. Simulation estimates* of FDP vs. (\hat{M}, \hat{T}) **

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

**To properly read this figure, print in color

The area circled in red on Figure 26 shows non-monotonic behavior and missing points. This area, having the tightest firing rules, has a very low rate of salvo declarations (false or positive). The low rate of declarations (see next figure for the rate of false declarations) makes the statistics highly variable, and in some cases the ratio cannot be computed at all as there are no declarations during the run. This makes exploring the region of low false declaration probability hard to do.

Figure 27 presents an MOE which may be more useful operationally - the number of false salvo declarations per unit time (Hour) - FDR. This translates to the rate of missiles launched unprovoked per hour.

Figure 27. Simulation estimates* FDR vs. (\hat{M}, \hat{T}) **

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

**To properly read this figure, print in color

3. Results of the Base Case Scenario

Dumb missile

Figure 28, Figure 28 and Figure 29 present the probability of success the FDR and FDP for different firing rule pairs (\hat{M}, \hat{T}) . The missile is “Dumb” and the scenario is as in Figure 25

The probability of success is defined here as in Chapter III. The simulation estimate for the probability of success is the ratio between the number of salvos the attacker has been killed and the total number of salvos.

Figure 28. Simulation estimates* for the Probability of success vs. \hat{T} (in seconds) for different values of \hat{M} (“Dumb” missile)**

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

**To properly read this figure, print in color.

Figure 29. Simulation estimates* of FDR vs. \hat{T} (in seconds) for different values of \hat{M} **

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

**To properly read this figure, print in color.

Figure 30. Simulation estimates* of FDP vs. \hat{T} (in seconds) for different values of \hat{M} **

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

**To properly read this figure, print in color.

For clarity of presentation only the cases $\hat{M} \geq 2$ are presented in Figure 28. We can see in Figure 27 that for the case $\hat{M} = 1$ the value of FDR is simply the rate of false detections as expected. We have not defined the defender's acceptable value of FDR, but it seems obvious that choosing $\hat{M} = 1$ (effectively responding to the first detection) is unacceptable due to the high value of FDR ($4_{[FD/Hr]}$). The highest probability of success (~ 0.55) may be achieved when $\hat{M} = 2$ however when $\hat{M} = 2$ there is still a significant FDR. Since the FDR is monotone increasing with \hat{T} , we may want to choose \hat{T} slightly above 5 seconds. This will give the lowest value of FDR possible ($0.02_{[FD/Hr]}$) for a non

zero probability of success (~ 0.45). Alternatively the defender may decide to settle for lower probability of success and choose ($\hat{M} = 3, \hat{T} > 10$). The FDR is then close to zero ($< 0.005_{[FD/HR]}$) and the probability of success between 0.3 and 0.4.

Method 1: Ground Sensor Guided Missile

The following figure presents the simulation estimates of the probability of success for the ground sensor guided missile. The rest of the scenario is as in Figure 28

Figure 31. Simulation estimates* of the Probability of success for vs. \hat{T} (in seconds) for different values of \hat{M} (“Smart” ground sensor guided missile)**

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

**To properly read this figure, print in color.

Changing the missile type does not influence the FDR therefore we may still refer to Figure 28 and Figure 27 for the FDR. The most significant difference from Figure 28 is in the curves for $\hat{M} = 1$ and $\hat{M} = 2$ which reach considerably higher values. However this does not change the defender's decision considerably; the defender still has only two viable options $\hat{M} = 2$ and $\hat{M} = 3$. The defender may be more inclined to choose $\hat{M} = 2$ because of the increase in the probability of success.

Method 2; Onboard sensor Guided Missile

The following figure presents the probability of success for the onboard sensor guided missile; the sensor is "Passive" and receives 10 times less energy than the ground sensor. The rest of the scenario is as in Figure 28

Figure 32. Simulation estimates* of Probability of success for vs. \hat{T} for different values of \hat{M} ("Smart" onboard "Passive" sensor guided missile)**

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

**To properly read this figure, print in color.

Changing the missile type does not influence the FDP therefore we may still refer to Figure 28 and Figure 27 for the FDP. Changing from the “dumb” missile to an onboard “Passive” sensor missile does not affect the defender’s decision at all. It seems the only difference between Figure 28 and Figure 32 is in the curve for $\hat{M} = 1$ which is not an option because of the high FDR.

It seems given only these three options that the defender would choose to use the ground sensor guided missile, possibly using the firing rule pair $(\hat{M} = 3, \hat{T} > 10)$.

4. The Effect of the False Detection Rate

No False detections

Let us first look at the extreme case where the rate of false detections is zero. The following figure presents the simulation estimates for the probability of positive salvo declaration when there are no false detections (False detections are simply not scheduled in these simulation runs). Although there are no false detections the defender still implements the same firing rule. The rest of the scenario is the same as in Figure 28. Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

Figure 33. Simulation estimates* of Probability of positive salvo declaration vs. \hat{T} for different values of \hat{M} . No false detections **

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

When $\hat{M} = 1$, the probability of positive salvo declaration is always 1. For $\hat{M} > 1$ we notice there are sudden increases in the probability as \hat{T} is increased. Take for example the case where $\hat{M} = 2$. Recall the inter-firing time is uniformly distributed between 4.5 and 5.5 seconds. Therefore when the decision variable $\hat{T} < 4.5$ seconds, there is no combination of detected rockets within the salvo that can generate a salvo declaration. Any two detected rockets will be detected at a greater time interval than \hat{T} . However once $\hat{T} > 5.5$, every two consecutive detected rockets will fall within the time interval \hat{T} and therefore will trigger a salvo declaration. Notice that the first increase in the probability of salvo declaration for $\hat{M} = 2$ is about equal to the probability of detecting any combination containing at least two consecutive detected rockets, given by: $P = 1 - (1 - \alpha)^5 - 5 \cdot \alpha \cdot (1 - \alpha)^4 - 6 \cdot \alpha^2 \cdot (1 - \alpha)^3 - \alpha^3 \cdot (1 - \alpha)^2 = 0.8859$. As we increase

\hat{T} more combinations of detected rockets may generate a salvo declaration and so the probability of salvo declaration increases. The maximal probability of salvo declaration for $\hat{M} = 2$ (given when $\hat{T} > 20$) is about .997 which corresponds to one minus the probability of that no rocket is detected in the salvo given by: $P = 1 - (1 - \alpha)^5 = 0.9976$, the only combination which will not trigger a salvo declaration when $\hat{M} = 2, \hat{T} > 20$.

High Rate of False Detections

Let us now explore the effect of increasing the ground sensor's rate of false detections. The following figure presents the probability of success and the FDP. The mean time between false detection is 60 seconds. The rest of the scenario is the same as in Figure 28

Figure 34. Simulation estimates* for the Probability of success vs. \hat{T} (in seconds) for different values of \hat{M} ("Dumb" missile).High rate of false detections **

Figure 35. Simulation estimates* of FDP vs. \hat{T} (in seconds) for different values of \hat{M} .
High rate of false detections **

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

**To properly read these figures, print in color.

Increasing the rate of false detections increases the FDP (compare to Figure 26). False detections are the cause for false salvo declaration and so this result is expected. Comparing Figure 34 to Figure 28 we see that the probability of success is increased as well (this is most obvious when $\hat{M} = 5$). To understand the contribution of false detections to the probability of success, think of the case when $\hat{M} = 4$. When $\hat{M} = 4$ and in the absence of false detections, the firing rule demands for 4 rockets to be detected. The probability of this event is not very high ($N \cdot \alpha^4 \cdot (1 - \alpha) + \alpha^5 = 5 \cdot 0.7^4 \cdot 0.3 + 0.7^5 \cong 0.52$). Furthermore in the uniform distribution case, if the decision variable \hat{T} is low enough there will never be enough time for all 4 rockets to be fired within \hat{T} . This reduces further the probability of salvo declaration. Indeed we see that in figure Figure 28 when $\hat{M} = 4$ and $\hat{T} < (\hat{M} - 1) \cdot \mu_f = 15$ then the

probability of success is close to zero. However in the presence of false detections, fewer than 4 rockets in the salvo need to be detected for a salvo to be declared. Therefore increasing the rate of false detections increases the probability of salvo declaration and in turn the probability of success. Notice for $\hat{M} = 4$ and $10 < \hat{T} < 15$ in Figure 34 the probability of success is significant and not close to zero as in Figure 28. We learn from this discussion that the probability of success presented in Chapter III with no false detections, gives a lower bound on the maximal probability of success over \hat{T} for the case with false detections.

FDP has sudden drops at some values of \hat{T} . These drops correspond to sudden increases in the probability of success. As we have seen earlier increasing \hat{T} allows more combinations of detected rockets in the salvo to generate a salvo declaration. This suddenly increases the rate of positive salvo declaration but only slightly changes the rate of false salvo declarations. The net result is a sudden drop in the FDP.

The “wild” swings in the FDP for low values of \hat{T} when $\hat{M} = 5$ are due to simulation variability as explained in 4.C.2.

5. The Effect of the Missile Flight Time

The response of the probability of success to variations in the missile flight time has been shown in Chapter III in the case with no false detections. We have already concluded that the results in Chapter III give a lower bound on the maximal probability of success (over \hat{T}) with false detections. For relatively low rate of false detections, we expect the maximal values of the probability of success to be close to the ones in the case with no false detections. For instance, in Figure 28 the maximal probability of success when $\hat{M} = 2$ is about 0.55. Comparison of this value to the probability of success when $\hat{M} = 2$ and $\tau_m = 20$ in Figure 7 shows they are about the same. We can repeat this exercise for any value of \hat{M} and for any type of missile (comparing Figure 11 to Figure 31 and, Figure 19 to Figure 32). We demonstrate this one more time by changing the missile flight time to $\tau_m = 2$ and again comparing with Figure 7

Figure 36. Simulation estimates* of Probability of success for vs. \hat{T} for different values of \hat{M} (“Dumb” missile). $\tau_m = 2$ **

* Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos.

**To properly read this figure, print in color.

6. The Effect of the Salvos Rate

Let us now explore the effect of increasing the rate of salvos. The following two figures present estimates of the probability of success and the FDP. Each estimate is from a single simulation run containing a sequence of 1000 rocket salvos. The mean time between salvos is 900 seconds (15 minutes), a substantial decrease from 2 hours. The rest of the scenario is the same as in Figure 28

Figure 37 and Figure 28 are the same. Increasing the salvo rate does not change the probability of success. Comparing Figure 37 and Figure 29 we notice the FDP drops dramatically. Recall the definition of a false salvo declaration basically says a false salvo declaration is a salvo declaration which occurs during the time between salvos. Decreasing the mean time between salvos means that for a given time interval during the

simulation run, there would be on average more salvos and less time during which false salvos may occur. Since the firing rule is unchanged the rate of positive salvo declarations during the salvo and the rate of false salvo declaration between salvos are unchanged. Overall the simulation run will have more positive salvo declarations and less false salvo declarations. The net result is a lower FDP. It is interesting to note that although the FDR has not changed the FDP has changed. If the defender is more concerned with the ratio of false to positive salvo declarations rather than the rate of false salvo declarations per unit time, he may choose a less conservative firing rule under a more intensive rocket attack. In other words when the attacker shoots more salvos, the defender may become more “happy trigger”. This last observation means that when the rate of salvo is higher, the defender may choose a more lenient firing rule. Perhaps in the case above the defender will choose $(\hat{M} = 2, \hat{T} = 6)$.

7. The Exponential Case

We now explore the case where the inter-firing time and escape time are exponentially distributed. The following two figures present the probability of success and the FDP. The inter-firing time and escape time are exponentially distributed with means 5 and 15 seconds respectively. The rest of the scenario is the same as in Figure 28

Comparing the exponential case to the uniform case (Figure 28 and Figure 28), we notice how in the exponential case the curves become smoother and have no sharp drops or increases as in the uniform case. The FDP does not present non monotone behavior when τ_m is very low. In the exponential case the probability of success is never zero no matter how demanding the firing rule is. Comparing Figure 39 to Figure 9 we can see again how the maximal probability of success over \hat{T} corresponds to the values of the probability of success with no false detections.

V. SUMMARY

In this thesis, we have explored and discussed tactical considerations in countering mortar and rocket fire, when the enemy has adopted a “shoot and scoot” tactic.

The probability of success – the probability of a timely effective hit of the attacker – is used as the MOE for the defender’s effectiveness. We have used the probability of false salvo declaration proportion (FDP) and the false salvo declarations rate (FDR) as MOEs for the defender’s chances of mistakenly firing a missile and increasing the collateral damage.

We have developed a tool for comparing different defender tactics and responses (firing rules). In Chapter III, we have used an analytic model under the assumption that there are no false detections (and hence zero FDP and FDR). This analytic model allowed us to quantify the defenders dilemma between waiting, gathering more information and increasing accuracy, and responding early at the expense of more information and with less accuracy.

The analytic model presented how the probability of success depends on the sensor’s probability of rocket detection, the missile flight time and the attacker’s interfering and escape time distributions.

We have explored a suggested new tactic where the defender launches his missile as soon as possible based on a rough estimate of the attacker’s location. The missile’s trajectory is later corrected and updated while the missile is airborne, using ground sensor guidance or different types of onboard sensors. The effectiveness of the suggested tactic depends on the parameters of the scenario; however it is most useful when the missile flight time is long compared to the mean salvo length and escape time.

In Chapter IV, we have introduced false detections to the model. To deal with this predicament we have built a simulation. The defender’s firing rule has been extended to account for false detections by introducing a sliding time window. The problem in Chapter IV was to find a firing rule which gives the highest possible probability of

success while keeping FDP and FDR as low as possible. It is surprising to note that the presence of false detections, actually contributes to the defender's probability of success. This happens because false detections trigger the defender to launch his missile in cases he otherwise wouldn't have, even though a salvo is ongoing (e.g. no rockets were detected). Of course this improvement comes at the cost of mistakenly firing missiles causing collateral damage.

We discussed the simulation results for a base case and varied the rate of salvos, the rate of false detections and the missile flight time for sensitivity analysis.

Follow-on research may include taking the salvo rate, inter-firing and escape time distributions from real life data and exploring the ideas presented in this paper on that data. It would also be interesting to survey existing weapons and sensors and their parameters to see if it is possible to use any of them for the new tactic suggested in this thesis.

APPENDIX A

Although the results for the Normal case are very similar to the results of the Uniform case, we present here for the purpose of completeness our results for the case where the inter-firing and escape time are Normally distributed.

There are $N = 5$ rockets in the salvo. The inter-firing time is normally distributed with mean 5 seconds and variance $\frac{1}{12}\text{sec}^2$. The time to escape is normally distributed with mean 15 seconds and variance $\frac{1}{3}\text{sec}^2$. Notice that the inter firing and escape time variances and means are the same as in Figure 1 The rest of the scenario is as in Figure 1

Figure 41. Probability of success for different missile flight times

Figure 42. Probability of a timely hit for different missile flight times and number of residual rockets*

* To properly read this figure, print in color.

As mentioned above comparing Figure 1 and Figure 2 with Figure 41 and Figure 42 we see that the results for the Normal case are very similar to the results of the Uniform case.
